Abstract

Recent observations of the polar mesosphere have revealed that waves with periods near two days reach significant amplitudes in both summer and winter. This is in striking contrast to mid-latitude observations where two-day waves maximise in summer only. Here, we use data from a meteor radar at Esrange (68° N, 21° E) in the Arctic and data from the MLS instrument aboard the EOS Aura satellite to investigate the wintertime polar two-day wave in the stratosphere, mesosphere and lower thermosphere. The radar data reveal that mesospheric two-day wave activity measured by horizontal-wind variance has a semi-annual cycle with maxima in winter and summer and equinoctial minima. The MLS data reveal that the summertime wave in the mesosphere is dominated by a westward-travelling zonal wavenumber three wave with significant westward wavenumber four present. It reaches largest amplitudes at mid-latitudes in the southern hemisphere. In the winter polar mesosphere, however, the wave appears to be an eastward-travelling zonal wavenumber two, which is not seen during the summer. At the latitude of Esrange, the eastward-two wave reaches maximum amplitudes near the stratopause and appears related to similar waves previously observed in the polar stratosphere. We conclude that the wintertime polar two-day wave is the mesospheric manifestation of an eastward-propagating, zonal-wavenumber-two wave originating in the stratosphere, maximising at the stratopause and likely to be generated by instabilities in the polar night jet.

1 Introduction

The quasi-two-day wave (Q2DW) is one of the most conspicuous features of the mesosphere and lower thermosphere (MLT) region. At middle and low latitudes the Q2DW reaches maximum amplitudes of several tens of  $\text{ms}^{-1}$  in late summer, where it can be the largest-amplitude feature present, but it is largely absent at other times (e.g., Muller et al., 1978). The summertime Q2DW is believed to be primarily a westward propagat-

ing, zonal wavenumber 3 (hereafter W3 etc.) wave. This has been identified with the (3, 0) Rossby normal mode (Salby, 1981) and baroclinic instabilities, if there is sufficient eastward shear above the summertime westward jets (Plumb 1983). Significant W4 components and somewhat smaller W2 components have also been reported in both observations and in modelling studies (e.g., Meek et al., 1996; Norton and Thuburn, 1996; Pancheva et al., 2004).

In contrast to these mid-latitude observations, recent studies have revealed significant wave activity with a period near two days in the winter Arctic MLT region (Nozawa et al., 2003a, b; Manson et al., 2004). These studies used ground-based meteor and MF radars to reveal significant wave amplitudes in winter, but were unable to determine the zonal wavenumber and direction of propagation of the wintertime polar two-day wave because they had insufficient longitudinal coverage in the radars used.

In the polar winter stratosphere, a two-day wave has been observed and identified as an eastward propagating, zonal wavenumber 2 (E2) planetary wave. This wave is believed to be one of a series of waves generated by barotropic instabilities in the polar night jet (e.g., Venne and Stanford, 1982; Hartmann, 1983; Prata, 1984; Lait and Stanford, 1988 and Manney et al., 1988). Nozawa et al. (2003b) suggested that the polar MLT-region wintertime two-day wave may be an E2 wave connected to these stratospheric oscillations – but this could not confirmed in the absence of longitudinal measurements.

Palo et al. (2007) reported an E2 wave in the mid-latitude, summer, southern-hemisphere MLT region occurring simultaneously with a W3 wave. They attributed the E2 wave to a non-linear coupling between the W3 Q2DW and the migrating diurnal tide.

Here, we investigate the nature of the wintertime polar two-day wave observed in the MLT region by an Arctic meteor radar and in data from the MLS (Microwave Limb Sounding) instrument aboard the NASA Aura satellite. In particular, the longitudinal coverage provided by the satellite observations allows us to determine zonal wavenumbers and the height coverage allows us to reveal the relation of this MLT-region wave to

two-day waves in the stratosphere. Finally, we address the mechanisms whereby this wave might be excited (e.g., non-linear coupling or excitation by barotropic instability).

## 2 Data analysis

Data from two independent sources are used in this study. The first source is measurements of horizontal winds at mesopause heights recorded by a meteor radar at Esrange (68° N 21° E). This radar measures the winds with typical height and time resolutions of about 3 km and 1 hour, respectively (See Mitchell et al., 2002 for details). The Esrange radar has operated continually from October 1999. Here, data from the interval October 1999 to April 2007 are considered and were analysed to yield hourly estimates of zonal and meridional winds in six height gates between 80 and 100 km.

The second source of data is the MLS instrument aboard the NASA Aura satellite - part of the A-train constellation of satellites (Waters et al 2006). Data from Aura over the interval August 2004 to February 2007 are considered here. MLS yields geopotential height as one of its level-2 data products covering the height range of ~ 10 – 97 km. The Aura satellite is in a Sun-synchronous orbit and so passes through only two local times at any given latitude. At the 68° N latitude of Esrange these local times are about 3.1 and 12.3 hours. The highest latitude accessible to the satellite is just over 80°.

Here, we have applied the data analysis method of Wu et al. (1995a), to the geopotential height data. In this method, the geopotential height data is divided into latitude bands of 10 degrees width (e.g. 60°–70° N). A data set is then assembled consisting of geopotential height values for successive passes of the satellite through each band. Because of the path of the satellite, the universal times and longitudes of the crossings through any given latitude band are not independent and, in fact, form a regular matrix. Sinusoidal functions of zonal wavenumber 4 to -4 and periods of 42 to 56 hours were then least-squares fitted to this matrix. This yields geopotential amplitudes and phases for waves with any combination of these wavenumbers and periods within a particular latitude band. Note that positive wavenumbers correspond to westward propagating

waves and negative to eastward propagating waves. Note that because there are only two local times within any latitude band, this analysis is unable to resolve tides without complications caused by aliasing.

### 3 Results

5 The radar data were analysed to produce a climatology of waves with period near two days. For a particular height gate, the horizontal winds were band-pass filtered to reveal oscillations with periods between 1.5 and 3.4 days. We assume that all of the variance in this band is associated with the Q2DW. For each month of data a variance value was calculated for each height gate. These variance values then provide a simple  
10 proxy of wave activity within this period band.

Figure 1a, b presents monthly variance values for zonal and meridional winds, respectively, measured over Esrange from a height gate spanning 89 to 92 km from October 1999 to April 2007. The Figure clearly shows that variance tends to maximises in winter and summer and has equinoctial minima, i.e. there is a semi-annual  
15 cycle. There is also considerable inter-annual variability. For instance, the summertime maximum varies from values as small as about  $20 \text{ m}^2 \text{ s}^2$  in 2001 and 2004 to values as large as about  $75 \text{ m}^2 \text{ s}^2$  in 2002.

This semi-annual behaviour is in marked contrast to that observed at middle and low latitudes where wave activity with a period near two days maximises in the summer and is significantly weaker in the winter.  
20

To reveal a representative seasonal cycle, a composite-year analysis was carried out using the data of Figure 1. Figure 2 presents this composite year analysis for the zonal and meridional components. The semi-annual cycle of variance is very apparent. In the case of the winter maximum, the zonal and meridional variances are about the  
25 same size and are  $\sim 40 \text{ m}^2 \text{ s}^2$ . However, in the case of the summer maximum the meridional variance is significantly larger than the zonal, some  $\sim 60 \text{ m}^2 \text{ s}^2$  c.f. some  $\sim 35 \text{ m}^2 \text{ s}^2$ . In both zonal and meridional cases the equinoctial minimum have values of

Interactive Discussion

about  $\sim 15 \text{ m}^2 \text{ s}^2$ .

These results suggest that there is considerable wave activity with a period near two days present in the Arctic winter and summer. This reinforces the conclusions of Nozawa et al. (2003a, 2003b) and Manson et al. (2004).

The MLS data provide an opportunity to investigate the zonal wavenumber(s) and global context of these wave features evident in the summer and winter Arctic mesosphere. For each 10 degree latitude band from  $80^\circ \text{ N}$  to  $80^\circ \text{ S}$ , the average geopotential height amplitude was calculated over the period range 42–56 h. These averages were calculated using a time window of 15 days incremented through the data set in steps of 5 days. The calculation was performed for zonal wavenumbers W4 to E4.

The result of this analysis is an estimate of wave amplitude against latitude and time for each of the wavenumbers W4 to E4 over the interval August 2004 to February 2007. Figure 3a–d presents these results for zonal wavenumbers W4, W3, W2 and E2 at a height of about 90 km (selected to match the radar observations). Results for wavenumbers W1, 0, E1, E3 and E4 are not shown because these yielded negligible amplitudes (generally less than 40 m). In each Figure, the contours are plotted only for amplitudes larger than 40 m.

We will now consider each Figure in turn. The W4 results of Fig. 3a reveal amplitudes that maximise in each hemisphere at mid-latitudes during the summer. Wave amplitudes are strongest during the months of June to August in the northern hemisphere and December to February in the southern hemisphere. Amplitudes reached values of  $\sim 140 \text{ m}$  in each summer, except in summer 2006 in the northern hemisphere which reached  $>200 \text{ m}$ . Note that there are no significant amplitudes ( $>40 \text{ m}$ ) in winter in either hemisphere. Further, note that the amplitudes are small at latitudes poleward of  $\pm 60^\circ$  in each hemisphere.

The W3 results of Figure 3b reveal amplitudes which also maximise in each hemisphere at mid-latitudes during the summer. In this case, however, the summertime southern-hemisphere amplitudes are significantly larger than in the northern hemisphere. Wave amplitudes are strongest during the months of June to August in the

Interactive Discussion

northern hemisphere and January and February in the southern hemisphere. In the northern hemisphere, amplitudes reach values of  $\sim 140$  m. However, in the southern hemisphere, peak amplitudes exceed 250 m in each of the three summers observed. Note again that there are no amplitudes  $>40$  m in winter in the southern hemisphere.

5 There are, however, bursts of activity in the northern hemisphere at mid-latitudes during each winter. These bursts reach amplitudes as large as 90 m, but are in all cases smaller than the summertime amplitudes. Again, note that the amplitudes are small at latitudes northwards of  $60^\circ$ . However, in the southern hemisphere, significant amplitudes are present to latitudes as far south as  $-75^\circ$ .

10 The W2 results of Fig. 3c reveal a rather similar picture to that of the W3. Again, although there are amplitude maxima in each hemisphere during the summer, there is also activity of equivalent amplitude in the northern hemisphere winter. In the southern hemisphere, wave amplitudes are strongest during the months of December to February. The amplitudes reach values of  $\sim 100$  m in both the northern and southern hemisphere. The oscillations extend as far polewards as  $\pm 70^\circ$ .

15 The E2 results of Fig. 3d reveal a rather different picture. In contrast to the other wavenumbers, the amplitude of E2 maximises in both hemispheres during the winter. There is also significant activity in the southern hemisphere summer, which may be an effect of aliasing from the W3 since these maxima occur at the same time as those of the W3 (see Sect. 4). The E2 activity generally occurs poleward of  $\pm 50^\circ$ . Wave amplitudes are strongest during the months of November to February for the northern hemisphere and June to August plus January for the southern hemisphere. Amplitudes reach values of  $\sim 100$  m in both hemispheres.

20 To see if these observations can explain the behaviour observed over Esrange (Fig. 1), the data were reanalysed to examine the latitudes from  $63^\circ$  to  $73^\circ$  N at a height of  $\sim 91$  km. The monthly variances of two-day wave activity as observed by the radar are shown in Fig. 4a for the August 2004 to February 2007 interval for which Aura MLS data are considered. Figure 4b, c presents the corresponding time series of geopotential heights over this latitude range. The W3 and E2 results are shown in

Interactive Discussion

Fig. 4b and the W4 and W2 results in Fig. 4c.

During winter, the greatest activity (geopotential amplitude) is present in the E2 component and there is some activity in the W3. However, because of the effect of aliasing we do not believe this wintertime W3 activity is significant (see Sect. 4). The summertime activity seems to be a combination of the W3 and W2, with only small contributions from the W4 and E2. These results show that the summer time and winter time polar two-day wave have very different wavenumbers, i.e., largely W3 and E2, respectively.

Prata (1983) showed that there is a wintertime, E2 polar two-day wave in the stratosphere. To determine if this wave is connected to that observed here in the mesosphere, we examined the MLS results from 10 to 100 km and 63° to 73° N. Figure 5 presents time-height contours of the geopotential amplitude of the E2 two-day wave calculated as 15-day means. The Figure clearly shows that the wave observed in the mesosphere is also present to heights below 30 km and reaches maximum amplitudes at heights of about 60 km, i.e., near the stratopause. This means that the MLT-region and stratospheric observations are almost certainly observations of a single E2 planetary wave that is present at heights from below 30 km to above 100 km.

The wintertime occurrence of this E2 wave can be explained in terms of the Charney and Drazin theorem (1961). The zonal phase speed,  $c_x$ , of the E2 two-day wave at the 68° N latitude of Esrange is  $\sim 52 \text{ ms}^{-1}$ . Charney-Drazin theorem states that a planetary wave can only propagate for  $c_x$  values such that  $0 < \bar{u} - c_x < U_c$ , where  $\bar{u}$  is the zonal mean wind and  $U_c$  is the critical speed, which is  $28.6 \text{ ms}^{-1}$  (for this latitude and assuming an E2 wave of meridional wavenumber 2) e.g., Forbes (1995). This means that the E2 two-day wave should only be able to propagate in regions where the zonal wind speed lies between  $\sim 52$  and  $80.6 \text{ ms}^{-1}$ . To see if this is actually the case in our observations, we calculated the zonal mean zonal winds from the UKMO assimilated stratospheric data for the October 2004 to February 2007 interval corresponding to the Aura MLS data. To match these to the MLS observations they were calculated as 15-day means within the 63°–73° N latitude range. The results of this analysis are not shown, but the boundaries of these regions are indicated on Figure 5 by dashed lines.

Interactive Discussion

It is immediately clear from the Figure that most of the E2 two-day wave activity occurs only within these regions. This relation to the mean wind provides compelling support for the interpretation of the E2 two-day wave as a planetary wave. Note that the dashed lines do not extend above  $\sim 65$  km because this is the upper limit of the UKMO analyses ( $\sim 55$  km after March 2006).

Finally, the vertical gradients of phase in the MLS observations were used to calculate the vertical wavelength of the polar wintertime E2 two-day wave. Typical vertical wavelengths were found to be  $123 \pm 9$  km.

From the above analyses, we conclude that the polar wintertime mesospheric two-day wave is dominated by an E2 two-day wave planetary wave, which extends through the stratosphere and mesosphere.

## 4 Discussion

Satellite studies of planetary waves can be complicated by aliasing because the longitude and time of observation are not independent (e.g., Wu et al., 1995a). The data can therefore have the same pattern present for multiple wavenumber-period combinations. In particular, a W3 two-day wave, could alias to an E2 two-day wave. The magnitude of the signal produced by aliasing depends on the difference in longitude between the ascending and descending nodes of the satellite's orbit. It can be shown using the method described by Wu et al. (1995a) that in our observations up to about 36 % of the amplitude of the E2 two-day wave would be aliased into the W3 two-day wave at  $68^\circ$  N, and visa-versa. This means that during the winter, when the E2 amplitude is actually more than 200% that of the W3 (Fig. 4b), it is not likely that the E2 signal contains a significant aliased component of the W3. Further, the observation that the E2 obeys Charney-Drazin theorem is also indicative that it is a real wave and not a result of aliasing. We therefore conclude for these two reasons that the observed E2 two-day wave does not contain a significant aliased component – at least in winter.

However, we note that in winter 2004/05 and 2006/07 the W3 amplitudes are about

Interactive Discussion

one-third those of the E2 and so we cannot be confident that the W3 signal is not entirely caused by aliasing from the E2.

Prata (1984) reported observations of an E2 two-day wave in the polar winter stratosphere. Prata's observations were only made at a height of  $\sim 45$  km. Our radar and satellite observations reveal that this wave extends to at least 100 km and that maximum amplitude occur at  $\sim 60$  km.

Two mechanisms have been proposed for the excitation of the E2 two-day wave in the stratosphere and/or mesosphere. Firstly, Hartmann (1983), Prata (1984), Lait and Stanford (1988) and Manney et al. (1988) suggest that the stratospheric E2 two-day wave is one of a series of waves generated by instabilities in the zonal winds of the polar night jet. Secondly, Palo et al. (2007) reported observations of an E2 two-day wave in the summer mesosphere, which they attributed to a nonlinear coupling between the W3 two-day wave and a migrating diurnal tide.

Our observations suggest that the wintertime polar two-day wave is an E2 wave which has propagated upwards from the stratosphere. However, it is unlikely to have been generated by the non-linear mixing of a W3 and a diurnal tide because the W3 amplitudes observed can be explained entirely as a result of aliasing.

## 5 Conclusions

Observations of mesospheric winds over Esrange ( $68^\circ$  N) reveal planetary waves with a period near 2 days in summer and in winter. The wintertime two-day wave is much stronger than that observed at mid-latitudes in winter and we have investigated its structure and origin. Observations made with the Aura MLS instrument reveal the winter two-day wave to be an eastward-propagating zonal wavenumber two planetary wave. Although there is a W3 wave present in the winter, aliasing considerations suggest this is likely to be a product of aliasing from the E2 wave rather than a genuine oscillation. The E2 appears to be small in the summertime, which instead is dominated by the classical W3 structure.

Interactive Discussion

Because the wintertime W3 wave has negligible amplitude, this suggests that the wintertime E2 wave is not generated by non-linear interaction between the W3 and the migrating diurnal tide at mesospheric heights, but rather has been generated in the stratosphere and has ascended to the mesosphere. This interpretation is reinforced by the observation of large E2 amplitudes around the polar winter stratopause. This E2 wave appears to be the mesospheric manifestation of the E2 wave observed in the stratosphere by Venne and Stanford (1982), Hartmann (1983), Prata (1984), Lait and Stanford (1988) and Manney et al. (1988), the generation of which is attributed to instabilities in the polar night jet.

We therefore suggest that although “two-day” wave activity is observed at polar latitudes in both summer and winter, the explanation for the summer and winter waves is different. The summer two-day wave appears to have the expected W2, W3 and W4 wave structure, whereas the winter two-day wave is largely or entirely an E2 wave originating in the stratosphere.

**The wintertime  
two-day wave**

D. Sanford et al.

a)

**Fig. 1a.** Monthly variances of band-passed horizontal winds from the Esrange meteor radar. The data are from heights of 89 to 92 km and have been band passed between periods of 1.5 and 3.4 days. a) zonal winds and b) meridional winds. The solid vertical lines indicate the boundary between each year. The dashed lines indicate 1 July .

**The wintertime  
two-day wave**

D. Sanford et al.

**Fig. 3.** Geopotential height amplitudes as a function of time and latitude for Aura MLS data at a height of  $\sim 90$  km, for oscillations with periods between 42 and 56 h and different zonal wavenumbers. **(a)** westward 4, **(b)** westward 3, **(c)** westward 2 and **(d)** eastward 2. Amplitudes below 40 m are not plotted. The solid vertical black lines indicate the boundary between years.

**The wintertime  
two-day wave**

D. Sanford et al.

**Fig. 5.** Time-height contours of geopotential-height amplitudes for an E2 wave of period 42–56 h. The latitude range is 63° and 73° N. The dashed lines indicate the  $52 \text{ ms}^{-1}$  zonal wind line derived from UKMO stratospheric assimilated data, above which Charney-Drazin theorem predicts the wave will propagate.
